GENERALIZED GEOMETRIC STRUCTURE OF THE MARGINAL  
DISTRIBUTIONS IN EVENT PROCESSES

Richard V. Evans

#349

1.  $\frac{1}{x^2} = x^{-2}$   
2.  $\frac{d}{dx} x^{-2} = -2x^{-3}$   
3.  $= -2x^{-3}$   
4.  $= -\frac{2}{x^3}$

Answer:

1.  $\frac{1}{x^2} = x^{-2}$   
2.  $\frac{d}{dx} x^{-2} = -2x^{-3}$   
3.  $= -2x^{-3}$   
4.  $= -\frac{2}{x^3}$

Answer:  $-\frac{2}{x^3}$

Generalized Geometric Structure of the Marginal  
Distributions of Vector Processes

Richard V. Evans  
Professor, Business Administration

Summary: The states of vector valued congestion processes with nearest neighbor transitions are divided into a sequence of sets  $A_i$ . The marginal distributions  $G_i$  are divided into a family of functions  $g_i^j$  so that  $dG_i^{i+1} = L_i(dG_i^j)$ . Recursive calculations provide the form of the linear functions  $L_i$  and the boundary function  $g_i^0$ .

This paper continues the study of a general family of congestion processes [2]. The state of the system is defined as a vector  $N(t), W(t)$ .  $N(t)$  is a finite dimensional vector with non-negative integer coordinates.  $W(t)$  is a  $k^*$  dimensional vector of elapsed times of each of  $k^*$  possible intervals which may be in process at time  $t$ . For each value  $n$  of  $N(t)$  a  $k^*$  dimensional vector  $S_n$  is defined. It has a 1 in the  $i$ th coordinate if the  $i$ th type interval is in progress when  $N(t) = n$  and a 0 otherwise. If  $N(t) = n$  and no interval terminates in  $t$  to  $t + \tau$ ,  $W(t + \tau) = W(t) + \tau S_n$ . Each of the  $i$ th type intervals is assumed to be a random variable with distribution function  $F_i(t), F_i(0) = 0$ , continuous density  $f_i(t)$ , and a finite mean. If an event of type  $i$  occurs when  $N(t) = n$  and  $W(t) = w$  there is a change in the value of  $N(t)$  from  $n$  to  $n'$  and  $w$  becomes  $w'$  according to a set of routing probabilities  $p_i(n, w, n', w')$  which are continuous from the right in  $w$  and sum to 1 for each  $i, n$ , and  $w$ . The  $i$ th coordinate of  $w'$  becomes 0 indicating that either a new interval of the  $i$ th type is begun or that when  $N(t) = n'$  no interval of type  $i$  is in process. In addition this change may cancel the  $j$ th type interval so that  $w'_j = 0$  or it may interrupt the interval so that the  $j$ th coordinate of  $S_n$  is 0 and  $w'_j = w_j$ . The change to  $n'$  may be the start or continuation of any number of intervals which were either not in process or suspended while  $N(t) = n$ . Finally the routing probabilities are positive only for  $n'$  for which  $|n' - n| = 1$  where the norm is the maximum of the absolute values of the coordinates. This is the nearest neighbor assumption which is the basis of the analysis.

This paper will examine the marginal distributions of the process which often provide sufficient information about the nature of the process. Let these distributions be  $G_t(n, w)$  with  $dg_t(n, w)$  the probability that  $N(t) = n$  and  $W(t)$  is approximately  $w$ . The event structure provides a simple justification for a recursive relationship in  $n$ . This approach was first used in

queuing by Winston [5] and then by Evans [1].

Sets of states

To use the nearest neighbor property, first the possible values of  $N(t)$ ,  $W(t)$  are divided into sets  $A_j$ ,  $j = 0, \dots$ . These sets must have the property that if  $N(t), W(t) \in A_j$  then the last event of the interval  $(0, t)$  must have occurred at some time  $\tau$  at which  $N(\tau), W(\tau) \in A_{j-1} \cup A_j \cup A_{j+1}$ . The fact that except for a set of probability 0 there are a finite number of events in  $(0, t)$  guarantees that to the same accuracy there must be a last event in  $(0, t)$  [2]. This combined with the restriction that routing probabilities are only positive for pairs of values of  $N(t), W(t)$  for which  $|n-n'| \leq 1$ , makes the construction of a family of sets  $A_j$  feasible. Even in specific models there may not be an obvious unique partition. One possibility starts with  $A_0$  containing the value  $n=0$  and then defines  $A_j = \{n, w | n=n', j \text{ for some } n' \in A_{j-1}\}$ . Another possibility is  $A_0 = \{n, w | \text{at least one coordinate of } n \text{ is } 0\}$  and then use the same inductive definition of  $A_j$ .

Iterative Relationship

The probability equation is based on decomposing a transition from  $n, w \in A_0$  at time 0 to  $n', w' \in A_j$  at time  $t$  according to the possible number of events  $j$  in the interval. Each appropriate sequence of  $j$  events is decomposed into two parts: the time  $\tau$  until the event which causes the last departure from some  $n^* \in A_{j-1}$  and the time  $t-\tau$  until  $n', w'$  which occurs at time  $t$ . This gives

$$P_t^j(n, w, n', w') = \int_0^t \int_{A_{j-1}} P_{t-\tau}^{j-1}(n, w, n^*, w^*) P_{\tau}^1(n^*, w^*, n', w') d\tau$$

where

$P_t^j(n, w, n', w')$  is the probability of  $j$  event transition from  $n, w$  at 0 to  $n', w'$  and approximately  $w'$  at  $t$

and

$Q_t^{i,\alpha}(n^*,w^*,n',w')$  is the probability of a  $i$ -event transition from  $n^*,w^* \in A_{i-1}$  to the intervals  $(0,d_i)$  to  $n',w'$  and approximately  $v \in A_i$  without entering the state  $(n',w') \in (d_i, \infty)$ .

The existence of these probabilities does not raise difficulties since they involve appropriate sequences of a finite number of intervals. Summing over  $j$  produces

$$\sum_{j=0}^{\infty} P_t^j(n,w,n',w') = \sum_{j=0}^{\infty} \int_{n^*,w^* \in A_{i-1}} \int_{k=0}^{\infty} P_{t-t}^k(n,w,n^*,w^*) Q_{t-t}^{i,j-k}(n^*,w^*,n',w') dt$$

Reversing the summation operations produces

$$P_t^i(n,w,n',w') = \int_{n^*,w^* \in A_{i-1}} P_{t-t}^i(n,w,n^*,w^*) Q_{t-t}^i(n^*,w^*,n',w') dt$$

where  $P_t^i = \sum_{j=0}^{\infty} P_t^j$  and  $Q_{t-t}^i = \sum_{k=0}^{\infty} Q_{t-t}^{i,k}$

Assuming  $dG_0(n,w) = 0$  only for  $n,w \in A_0$  this result can be written as

$$dG_t^i(n',w') = \int_{n^*,w^* \in A_{i-1}} dG_{t-t}^i(n,w,n^*,w^*) Q_{t-t}^i(n^*,w^*,n',w') dt$$

This means that there is a family of linear functions  $L_t^i$  which map the functions  $dG_t^i(n^*,w^*)$  for  $n^*,w^* \in A_{i-1}$  into  $dG_t^i(n',w')$  for  $n',w' \in A_i$ .

Using this relationship requires more explicit terms for the taboo probabilities  $Q_t^i dt$ . These can be developed in terms of some less complicated probabilities. Define

$$B_t^{i,k}(n,w,n',w') = \text{probabilities that a sequence of } k \text{ events starting from } n,w \in A_{i-1} \text{ at time } 0 \text{ is completed in time } t \text{ and that } W(t), W(0) = n',w' \in A_i \text{ and } W(0), W(t) \in A_i \text{ for } 0 \leq t \leq t.$$

$$B_t^i = \sum_{k=0}^{\infty} B_t^{i,k}$$

$Z_t^{i,k}(n,w,n',w')$  = probability that a sequence of  $k$  events starting from  $n,w \in A_i$  at time 0 is completed in time  $t$  and that  $B(t), W(t) \in n',w' \in A_j$  and  $N(t), W(t) \in A_j$  for  $1 \leq \tau \leq t$ .

$U^i(n,w,n',w') dt$  = probability of an event occurring in  $dt$  causing the transition from  $n,w \in A_i$  to  $n',w' \in A_{i+1}$ .

$$U^i dt * Z_t^{i,u} = Q_t^{i,u+1} dt$$

$D^i(n,w,n',w') dt$  = probability of an event occurring in  $dt$  causing the transition from  $n,w \in A_i$  to  $n',w' \in A_{i-1}$ .

For each finite sequence of events the first exit from  $A_i$  and first reentry into  $A_i$  are well defined events. Thus

$$Q_t^{i,\alpha} dt = U^{i-1} dt * B_t^{i,\alpha-1} + \sum_{j=2}^{\alpha-3} \sum_{k=1}^{j-1} \int_0^t \int_0^\tau U^{i-1} dt * B_t^{i,k} * Q_{\tau}^{i+1,j-k} dt * D^{i-1} dt * Z_{t-\tau}^{i,\alpha-j}$$

For simplicity of notation, the sums and integrals over states have been suppressed in the operation\*. The limits on the event sums reflect the fact that it requires two events to enter  $A_{i+1}$  and return to  $A_i$ . All one and two event sequences whose probabilities must be included in  $Q_t^{i,\alpha}$  never leave  $A_i$  after entering it. Now summing over the number of events,

$$Q_t^i dt = U^{i-1} dt * B_t^i + \sum_0^{\alpha-1} \int_0^t U^{i-1} dt * B_{\tau}^{i+1} dt * D^{i-1} dt * Z_{t-\tau}^i$$

This equation can be solved iteratively using

$$\alpha Z_t^i = B_t^i$$

$$k Q_t^i = U^{i-1} * Z_t^i$$

$$k Z_t^i = B_t^i + \int_0^t \int_0^{t-\tau} B_{t-\tau-\tau}^i * Q_{t-\tau-\tau}^{i+1} + B_{t-1}^i d\tau * \int_0^{t-1} Q_{t-1}^i$$

The validity of this iterative scheme is most obvious from its probabilistic interpretation. The parameter  $k$  denotes the maximum number of entries into  $A_{j+1}$  of the event sequences considered in each approximation. This means that the sequence of approximations is monotone non-decreasing and converges because the number of events in  $\tau$  is finite with probability 1.

A more interesting version of the preceding equation results from taking Laplace transforms so that the convolutions become products. A related equation occurs if the interest is focused on stable distributions.

Assuming that

$$\lim_{t \rightarrow \infty} dG_t^n(a, w) = dG_\infty^n(a, w)$$

then  $dG_t^i = dG_\infty^i(a, w)$  for  $a, w \in A_j$

The recursive relationship is

$$u G_t^{i+1} = Q_t^i + \int_0^t Q_{t-\tau}^{i+1} d\tau$$

The integrals must converge so

$$\lim_{t \rightarrow \infty} \int_0^t u G_t^{i+1} * dG_{t-\tau}^i = \lim_{t \rightarrow \infty} \int_0^t u G_{t-\tau}^{i+1} * dG_{t-\tau}^i = 0$$

can converge only because  $dG_t^{i+1}$  converges to zero and states in  $A_{j+1}$  are transient.

The finiteness of the expected time spent in  $A_j$  before reentering  $A_{j+1}$ ,

$\int_0^\infty Q_t^i dt$  does not guarantee the existence of a limiting distribution. This

requires that  $dG_t^i$  converge and that the eigen values of these integrals as

functions of the  $dG^i$  be less than 1 for enough values of  $i$  so that  $\sum dG^i$  exists.

Most queueing system models have event and routine sequences which effect transitions from any state  $(n, w)$  to any other state  $(n', w')$  in finite time with positive probability. Usually this is sufficient to establish that for  $i \geq 1$

$$1) \int_0^{\infty} B_t^i dt \leq D^i * L^{i+1} + \int_0^{\infty} R_t^i * D^i * L^{i+1} dt$$

and

$$2) \int_0^{\infty} B_t^i dt \leq U^i * L^{i-1} \leq L^i$$

where  $B < 1$  and  $L^i(n, w) = 1$  for all  $(n, w) \in A_i$ .

The first requirement is that from an  $(n, w)$  in  $A_i$  the system eventually leaves  $A_i$ . Since  $D^i$  and  $U^i$  are finite this means that the expected length of stay in  $A_i$  must be finite; i.e.  $\int_0^{\infty} B_t^i dt$  is finite for all  $(n, w)$  in  $A_i$ . The second requirement is that the exit is not always to a state  $A_{i+1}$ . These properties guarantee that  $\int_0^{\infty} Q_t^i dt$  converges. The argument is perhaps easiest to describe in terms of the functions  $Z_t^i$ .

Integrating the iterative definition of  $Z_t^i$  with respect to time

$$\int_0^{\infty} Z_t^i dt = \int_0^{\infty} B_t^i dt + \int_0^{\infty} \int_0^t \int_0^{\tau} B_{t-\varepsilon}^i * D^i d\varepsilon * \int_0^{\tau} Z_{t-\varepsilon}^{i+1} * D^{i+1} d\tau * \int_0^{\tau} Z_{t-\varepsilon}^{i-1} dt$$

Rearranging the integration

$$\int_0^{\infty} Z_t^i dt = \int_0^{\infty} B_t^i dt + \left[ \int_0^{\infty} B_t^i * D^i dt \right] * \left[ \int_0^{\infty} Z_t^{i+1} * D^{i+1} dt \right] * \left[ \int_0^{\infty} Z_t^{i-1} dt \right]$$

By induction on  $k$  for all  $i$

$$\begin{aligned} \int_0^{\infty} Z_t^i dt &\leq D^i * L^{i-1} = \int_0^{\infty} B_t^i dt * D^i * L^{i-1} \\ &+ \left[ \int_0^{\infty} B_t^i * D^i dt \right] * \left[ \int_0^{\infty} Z_t^{i+1} dt \right] * \left[ \int_0^{\infty} Z_t^{i-1} dt * D^i * L^{i-1} \right] \\ &\leq \int_0^{\infty} B_t^i dt * D^i * L^{i-1} + \int_0^{\infty} B_t^i * D^i dt * L^{i+1} \\ &\leq L^i \end{aligned}$$

and

$$\int_0^\infty k Z_t^i dt * L^i = \left[ \int_0^\infty B_t^i dt + \int_0^\infty B_t^i * U^i dt \right] * \left[ \int_0^\infty Z_t^{i+1} * D^{i+1} dt \right] * \left[ \int_0^\infty k^{-i} Z_t^i dt \right] * L^i$$

$$= \left( \int_0^\infty B_t^i dt * L^i + \int_0^\infty B_t^i * U^i dt \right) * \left( \int_0^\infty Z_t^{i+1} dt \right) L^{i+1}$$

$$= \int_0^\infty B_t^{i+1} dt * L^{i+1}$$

As k goes to infinity the bound on the process is removed.

The construction shows the existence of a stationary solution to the equation. The solution found for the linear case equation is also the only one which has the additional properties which are required for Q to have probabilistic meaning. First  $Z_t^i$  must be non negative. For any non negative measure W,  $W * Z_t^i$  must be a non negative measure. Conversely, for any non negative function V,  $Z_t^i * V$  must be a non negative function. In addition  $\int_0^\infty Z_t^i * D^i * L^{i+1} = L^i$  since the probability of returning to  $k_t$  must not exceed 1. Finally  $Z_t^i(0, \infty, \infty, 0) \leq Z_t^i(0, \infty, 0, \infty)$  since  $Z_t^i$  is less restricted than  $B_t^i$ . Let  $W_t^i$  satisfy these conditions and the equation. Compare  $W_t^i$  with the sequence  $k_t Z_t^i$  produced by the iterative process.

$$W_t^i - k_t Z_t^i = \int_0^t \int_0^s B_t^i * U^i dt + (W_{t-\xi}^{i+1} - k_{t-\xi}^{i+1} Z_{t-\xi}^{i+1}) * D^{i+1} dt + (W_{t-\xi}^i - k_{t-\xi}^i Z_{t-\xi}^i)$$

By induction  $W_t^i - k_t Z_t^i = 0$  for all  $t$  if  $W_t^{i+1} = B_t^{i+1}$  and by assumption  $W_t^i = B_t^i$ .

Let  $(W_t^i - k_t Z_t^i) * D^i * L^{i+1} = F_t^i$ . By induction  $F_t^i = F_t^{i+1} = 0$ . Again by

$$\text{induction } (W_t^i - k_t Z_t^i) * D^i * L^{i+1} = \int_0^t \int_0^s B_t^i * U^i dt * L^{i+1} = BL^i.$$

Repeating the induction  $(W_t^i - k_t Z_t^i) * L^{i+1} = F_t^i$ . Because of the non negativity this means that  $k_t Z_t^i$  converges to  $W_t^i$  and that  $W_t^i$  is the only probabilistically meaningful solution of the equation.

Phase type intervals

In a previous unpublished version of this discussion, the author began with the infinitesimal generator of these processes. A reader remarked that congestion processes were derived from mark chains any processes. That point

of view has been used here and has the advantage of making the arguments elementary. There is one questionable aspect of this, for the routing part of the process may be so inextricably meshed with the congestion process that its separation from the congestion process is a matter of abstraction. This is especially true if the routing is done in a way designed to estimate some measure of the future performance of the system. It is possible, however, to simultaneously discover the optimal routing policies as well as the nature of the congestion process.

There is another modification of the process which raises similar questions. Suppose that some or even all of the interval variables are phase-type random variables. Such variables are characterized by a finite number of exponential phases or sub-intervals. At the end of each phase either the interval terminates or another phase is begun. The conditional probabilities of these alternatives depend only on the phase just completed. The phases need not be ordered and identically distributed as is required for such interval distributions. The natural congestion process uses a discrete supplementary variable which identifies the number of phases completed since the start of the interval. If the routing process depends only on the congestion and not on the time since the start of the interval intervals, the congestion process can be studied in terms of the integer-valued Markov or valued process  $N(t)$ . This process may be partially observable if the phases may have no physical identity. This process can, of course, be studied by conditioning on the number of transition events in an interval. Introducing discrete supplementary variables increases the number of values of the integer-valued variable in the sets  $A_j$  but also allows the fundamental flow probability equation to become independent of the continuous supplementary variables. In this case the limiting behavior of the system can be analyzed in terms of vectors and matrices although they may have to be infinite dimensional. Such is the case when the number of states in the sets  $A_j$  is infinite. This method

may be the best method for handling continuous variables (often discrete so that digital computers may be used to model them). One of the reasons for this discussion is to present a method for dealing with both continuous supplementary variables and discrete variables.

Boundary Set  $A_0$

Piecewise linear models (see [1] for a discussion of models [3]) is the general model class of stochastic processes. The difference for fundamental difference is that they assume  $P_{ij}$  depends on some events (system empty, which has no associated supplementary variables). This model bypasses the assumption of some form of exponential interarrival times. However, stationary probabilities are then developed as multiples of the probability that the system is empty. They exploit a nearest neighbor simulator by developing probabilities recursively in terms of the number of events since the system was empty. This is similar to the recursive development probabilities presented in [2]. The single system empty state has the advantage that its limiting probability can be found by first assigning it a value  $\epsilon$ , then performing the recursive calculation, and finally assuming  $\epsilon \rightarrow 0$  so that the probabilities sum to 1. This is the classic approach of the difference equation analysis of limiting probabilities in M/G/1. It is possible that  $A_0$  can contain a number of values of  $W(t)$  and some of them will have associated supplementary variables. This leads to a more general expression for  $dG_{\mathbf{t}}^0$ . Again one can proceed through the number of events, ignoring out the last departure from  $A_0$ . Summing over the number of events gives

$$dG_{\mathbf{t}}^0 = dH_{\mathbf{t}}^0 * R_{\mathbf{t}}^0 + \sum_{i=1}^{I-1} dG_{\mathbf{t}}^0 + \sum_{i=1}^{I-1} P_{i+1}^0 * P_{i+1}^0 + \dots + P_{I+1}^0$$

The limit of the expression gives

$$dG_{\infty}^0 = dG_0^0 B_{\infty}^0 + \int_0^{\infty} \int_0^{\infty} dG_{\tau}^0 * U^0 d\tau * Z_{\tau+1}^1 * D^1 dt * B_{\tau}^0$$

In interesting cases it is impossible to remain in  $A_0$  indefinitely and  $B_{\infty}^0$  is the zero operator and  $\int_0^{\infty} B_{\tau}^0 dt$  is finite. In this case since  $Z_{\tau}^1$  must also be integratable and

$$dG_{\infty}^0 = dG_{\infty}^0 * U^0 * \int_0^{\infty} Z_{\tau}^1 dt * D^1 * \int_0^{\infty} B_{\tau}^0 dt$$

or

$$dG_{\infty}^0 = dG_{\infty}^0 * \int_0^{\infty} Q_{\tau}^1 dt * D^1 * \int_0^{\infty} B_{\tau}^0 dt$$

This suggests choosing  $dG_{\infty}^0$  as an arbitrary measure and iteratively calculating

$${}^k dG_{\infty}^0 = {}^{k-1} dG_{\infty}^0 * U^0 * \int_0^{\infty} Z_{\tau}^1 dt * D^1 * \int_0^{\infty} B_{\tau}^0 dt$$

or

$${}^k dG_{\infty}^0 = dG_{\infty}^0 * U^0 * \left[ \int_0^{\infty} Z_{\tau}^1 dt * D^1 * \int_0^{\infty} B_{\tau}^0 dt * U^0 \right]^{(k-1)} \int_0^{\infty} Z_{\tau}^1 dt * D^1 * \int_0^{\infty} B_{\tau}^0 dt$$

where the power  $k-1$  means repeat the \* operation  $k-1$  times. The expression  $\int_0^{\infty} B_{\tau}^0 dt * U^0 * D^1$  is the probability of leaving  $A_0$  for the various starting states and thus must be  $I^0$  if the limiting system results are to be strictly positive. Similarly  $\int_0^{\infty} Z_{\tau}^1 dt * D^1 * I^0$  is the probability of ever returning to  $A_0$  from states in  $A_1$ . These also must be  $I^0$  for all states in  $A_1$  or the system limit will be defective. Thus the operator in brackets must be strictly positive mapping all probability measures on the subset of  $n$  and values of the supplementary variables in  $A_1$  which can be entered in a transition from  $A_0$ . From positive operator theory [6] the repeated application of this to any non zero measure will produce a unique positive limit in the space of signed measures. Thus the entire iterative procedure will converge to such

a limit if  ${}^0dC_{ij}^0 * U^0$  is positive at least for some states. Moreover applying  $U^0 * L^1$  to both sides shows that  ${}^0dC_{ij}^0 = L^1 * L^1$  if  ${}^0dC_{ij}^0 * U^0 * L^1$ . This number is immaterial since it is irrelevant. Then the entire sum of probabilities is made equal to 1.

Degeneracy

So far this discussion has said little of the restricted nature of the changes in the supplementary variables. Thus the arguments can be adapted to more general assumptions should a situation require this. The assumptions about changes in the supplementary variables imply that both  $U^i$  and  $D^i$  are degenerate. They assign positive probability only to subsets of states. Because entry into  $A_i$  coincides with the termination of some interval, some supplementary variables must be 0 at entry times. Thus both of the sets  $A_i^U = \{(n', w') \mid (n, w) \in A_i, U^{i+1}(n, w, n', w') > 0 \text{ for some } (n, w) \in A_{i+1}\}$  and  $A_i^D = \{(n', w') \mid (n, w) \in A_i, D^{i+1}(n, w, n', w') > 0 \text{ for some } (n, w) \in A_{i+1}\}$  are strict subsets of  $A_i$ . This strict inclusion is even true of  $A_i^U \cup A_i^D$ . Within  $A_i$  there is a Markov process for which the initial distribution is concentrated in  $A_i^U \cup A_i^D$  and  $B_c^i$  is the transition operator.  $B_c^i * U^i$  and  $B_c^i * D^i$  exists from  $A_i$  to  $A_{i+1}$  and  $A_{i-1}$  respectively. Let  $B_{U,t}^i$  be the restriction of  $B_c^i$  to transitions from  $A_i^U$  to  $A_i$ ,  $B_{D,t}^i$  the restriction of  $B_c^i$  to transitions from  $A_i^D$  to  $A_i$ . These operators are all that are needed to study the corresponding restrictions  $Z_{U,t}^i$  and  $Z_{D,t}^i$  of  $Z_t^i$ . The restricted operators satisfy the equations

$$Z_{U,t}^i = B_{U,t}^i + \int_0^t \int_0^{\tau} B_{U,\xi}^i * U^i * Z_{U,t-\xi}^{i+1} * D^{i+1} * Z_{D,t-\tau}^i d\xi d\tau$$

$$Z_{D,t}^i = B_{D,t}^i + \int_0^t \int_0^{\tau} B_{D,\xi}^i * U^i * Z_{D,t-\xi}^{i+1} * D^{i+1} * Z_{D,t-\tau}^i d\xi d\tau$$

From the solution to these

equations the complete functions can be found (see

$$Z_U^i = B_U^i + \int_0^t \int_{V_U} B_U^i * U^i * Z_U^{i+1} + U^{i+1} * Z_U^{i+1} dt$$

Further formulae may be developed using either the Laplace transform or concentrating on the boundary conditions. Let us latter let the same symbols without the time subscript represent the integral of the operator with respect to time. In particular the equations become

$$Z_U^i = B_U^i + B_U^i * U^i + Z_U^{i+1} * U^{i+1} + Z_U^i$$

$$Z_D^i = B_D^i + B_D^i * U^i + Z_U^{i+1} * U^{i+1} + Z_D^i$$

Use the previous assumptions  $B_U^i * U^i * Z_U^{i+1} < L^{i+1}$  and  $Z_U^{i+1} * U^{i+1} * B_D^i \leq L^{i+1}$ . These guarantee that measures  $G^i$  for which  $B_U^i * U^i < L^i$  are mapped into measures  $G^{i+1}$  for which  $B_D^{i+1} * U^{i+1} < L^{i+1}$ . Thus the largest eigen value of  $B_U^i * U^i + Z_U^{i+1} * U^{i+1}$  is less than 1 which in turn guarantees an explicit solution to the second equation is

$$Z_D^i = \int_{r=0}^{\infty} (B_D^i * U^i + Z_U^{i+1} * U^{i+1})^r * B_D^i$$

or

$$Z_D^i = (I - B_D^i * U^i + Z_U^{i+1} * U^{i+1})^{-1} * B_D^i$$

where the power is repeated multiplication the inverse of the operator respectively.

Substituting this into the first equation gives

$$Z_U^i = B_U^i + B_U^i * U^i + Z_U^{i+1} * U^{i+1} + \int_{r=0}^{\infty} (B_D^i * U^i + Z_U^{i+1} * U^{i+1})^r * B_D^i$$

this can be rearranged as

$$Z_U^i = B_U^i * \int_{r=0}^{\infty} (B_U^i * U^i + Z_U^{i+1} * U^{i+1})^r * B_D^i$$

The operator series must converge and thus

$$Z_U^i = B_U^i (I - U^i * Z_U^{i+1} * U^{i+1} + B_D^i)^{-1}$$

or

$$Z_U^i = B_U^i + (1 - D) Z_U^{i-1}$$

This equation holds for  $i = 1, 2, \dots, n$ . If  $Z_U^0 = 0$ , it holds the last exit from  $U$  is  $Z_U^1 = B_U^1$ .

$$Z_U^i = B_U^i + (1 - D) Z_U^{i-1}$$

Restricting  $Z_U^i$  to  $U$  and  $Z_U^{i-1}$  to  $U$  gives the previous equation

$$Z_U^i = B_U^i + (1 - D) Z_U^{i-1}$$

$$k Z_U^i = B_U^i + (1 - D) Z_U^{i-1} \quad * \quad Z_U^{i+1} = 0$$

For all  $k$ ,  $Z_U^i \leq k Z_U^i$  since

$$\begin{aligned} Z_U^i - k Z_U^i &= (Z_U^i - k Z_U^i) = (Z_U^i - k Z_U^i) + (1 - D) Z_U^{i-1} - (1 - D) Z_U^{i-1} \\ &= (Z_U^i - k Z_U^i) + (1 - D) Z_U^{i-1} - (1 - D) Z_U^{i-1} \\ &= (Z_U^i - k Z_U^i) + (1 - D) Z_U^{i-1} - (1 - D) Z_U^{i-1} \\ &\leq 0 \end{aligned}$$

Also indeed, it shows  $Z_U^i \leq Z_U^{i+1}$  and  $Z_U^i \leq Z_U^{i+1}$  is monotone non decreasing and bounded in  $U$ . Let  $Z_U^i$  be the limit of  $Z_U^i$  which satisfies the equation  $Z_U^i = B_U^i + (1 - D) Z_U^i$ .

$$Z_U^i = \sum_{j=0}^{\infty} (1 - D)^j B_U^{i+j}$$

is well defined and well defined in  $U$  regardless of  $Z_U^i, Z_U^i$  satisfying the pair of equations. The same derivation for  $Z_D^i$  was derived. Thus the  $Z_U^i$  converges to  $Z_U^i$ .

M/M/1

Although successive approximations often provide feasible calculations for numerical analysis, it is instructive to examine at least one example in which complete analytic solution is possible. Obvious candidates for discussion are either M/G/1 or G/M/1 using only the single necessary supplementary variable. In these cases  $D^i$  and  $U^i$  are extremely degenerate since  $A_i^D = (i, 0)$  and  $A_i^U = (i, c)$  respectively. These special funneling states make it easy to solve for the  $Z^i$  which are all identical. The analysis easily provides limiting results in probability rather than the more familiar transform form.

In many ways more interesting here is the less general system M/M/1 in which the analysis uses supplementary variables  $w_1$  and  $w_2$  for both elapsed interarrival and service times respectively. The state space is partitioned according to sets  $A_i = \{(i, w_1, w_2) \mid w_1 \geq 0, w_2 \geq 0\}$ . The set  $A_0 = \{(0, w_1, w_2) \mid w_1 \geq 0, w_2 = 0\}$  is the obvious exception. When there is only one customer in the system, it is his service which is in process and this must have begun after his arrival which is also the last arrival. Thus  $A^1 = \{(1, w_1, w_2) \mid w_1 \geq w_2 \geq 0\}$  is also an exception. The degeneracy occurs because  $A_i^U = \{(i, 0, w_2) \mid w_2 \geq 0\}$ .  $A_i^D = \{(i, w_1, 0) \mid w_1 \geq 0\}$ . It is obviously important but not the extreme of a funneling state.

The operators which define the process are

$$B_t^0(w_1, 0, w_1', 0) = e^{-\lambda(w_1' - w_1)} dw_1'$$

$$B^0 = \int_0^\infty B_t^0 dt = e^{-\lambda(w_1' - w_1)} dw_1'$$

For all supplementary variable values for which it is defined and all  $i$  including  $i = 1$

$$B_t^i(w_1, w_2, w_1', w_2') = e^{-(\lambda + \mu)(w_1' - w_1)} \delta(w_1' - w_1, w_2' - w_2) dt$$

$$B^i = \int_0^\infty B_t^i dt = e^{-(\lambda + \mu)(w_1' - w_1)} \delta(w_1' - w_1, w_2' - w_2) dw_1'$$

where

$$\delta(x, y) = \begin{cases} 1 & x=y \\ 0 & x \neq y \end{cases}$$

For  $i \geq 0$

$$U^i(w_1, w_2, w_1', w_2') = \begin{cases} \lambda & \text{if } w_1' = 0, w_2' = w_2 \\ 0 & \text{otherwise} \end{cases}$$

For  $i \geq 1$

$$D^i(w_1, w_2, w_1', w_2') = \begin{cases} \mu & \text{if } w_2' = 0, w_1' = w_1 \\ 0 & \text{otherwise} \end{cases}$$

For the limiting distribution the solution to

$$Z_U^i = B_U^i + Z_U^i * U^i * Z_U^{i+1} * D^{i+1} * B_D^i$$

is the same for all  $i \geq 1$ . It is

$$Z_U = e^{-(\lambda+\mu)w_1'} \delta(w_1', w_2' - w_2) dw_1' + \lambda e^{-\lambda w_2' - \mu w_1'} \Gamma(w_2', w_1') dw_1' dw_2'$$

for

$$\Gamma(x, y) = \begin{cases} 1 & x \leq y \\ 0 & x > y \end{cases}$$

From this

$$Z_U * U = \lambda e^{-(\lambda+\mu)(w_2' - w_2)} dw_2' \Gamma(w_2', w_2') + \frac{\lambda^2}{\mu} e^{-(\lambda+\mu)w_2'} dw_2'$$

$$Z_U * D = \mu e^{-\mu w_1'} dw_1'$$

These combine to give

$$Z_U * U * Z_U * D = \lambda e^{-\mu w_1'} dw_1'$$

from which

$$Z_U * U * Z_U * D * B_D = \lambda e^{-\mu w_1' - \lambda w_2'} \Gamma(w_2', w_1') dw_1' dw_2'$$

For the distribution at the boundary the solution to

$$dG_\infty^0 = dG_\infty^0 * U^0 * Z_U^1 * D^1 * B^0$$

is

$$dG_{\infty}^0 = \lambda (e^{-\lambda w_1'} - e^{-\mu w_1'}) dw_1'$$

where the arbitrary scale factor has already been set so that

$$\int_0^{\infty} dG_{\infty}^0 = 1 - \lambda/\mu$$

In this way the recursive definition

$$dG_{\infty}^n = dG_{\infty}^{n-1} * U * Z$$

produces functions which sum to 1 as required for  $\lambda/\mu < 1$ , when the limiting distribution exists. For  $\lambda/\mu > 1$  the  $\Sigma dG^n$  does not converge. The explicit form for  $n$  is

$$\begin{aligned} dG_n^{\infty} = & (1 - \frac{\lambda}{\mu}) \left[ \sum_{i=0}^{n-3} \frac{\lambda^{n+1}}{\mu^{n-i-1}} \frac{(w_2' - w_1')^i}{i!} e^{-(\lambda+\mu)w_2'} + \right. \\ & \left. \frac{\lambda^n}{\mu^{(\lambda+\mu)}} \frac{(w_2' - w_1')^{n-2}}{(n-2)!} e^{-(\lambda+\mu)w_2'} \right] \Gamma(w_1, w_2) dw_1 dw_2 + \\ & \frac{\lambda^{n+1}}{\mu^{n-1}} e^{-\lambda w_2' - \mu w_1'} \Gamma(w_2', w_1') dw_1' dw_2' \end{aligned}$$

From this the marginal distributions in  $n$  and one supplementary variable are

$$\int_{w_2'=0}^{\infty} dG_{\infty}^n = (1 - \frac{\lambda}{\mu}) (\lambda^n / \mu^{n+1}) e^{-\mu w_1'} dw_1'$$

$$\int_{w_1'=0}^{\infty} dG_{\infty}^n = (1 - \frac{\lambda}{\mu}) \left( \frac{\lambda^{n+1}}{\mu^n} + \frac{\lambda^{n+1}}{\mu^{n-1}} \sum_{i=1}^{n-2} \frac{\mu^{i-1} w_2'^i}{i!} + \frac{\lambda^n (\lambda+\mu)}{\mu} \frac{w_2'^{n-1}}{(n-1)!} \right) e^{-(\lambda+\mu)w_2'} dw_2'$$

As anticipated marginal probabilities for the integer variable are

$$\int_0^{\infty} \int_0^{\infty} dG_{\infty}^n = (1 - \frac{\lambda}{\mu}) \frac{\lambda^n}{\mu^n}$$

and for the supplementary variables they are

$$\sum_{n=0}^{\infty} \int_{w_2'=0}^{\infty} dG_{\infty}^n = \lambda e^{-\lambda w_1'} dw_1'$$

and

$$\sum_{n=0}^{\infty} \int_{w_1'=0}^{\infty} dG_{\infty}^n = \mu e^{-\mu w_2'} dw_2'$$

The infinitesimal generator for this process is found from

$$dG_{t+\Delta t}^n(w_1, w_2) = (1-\lambda\Delta t-\mu\Delta t)dG_t^n(w_1-\Delta t, w_2-\Delta t) \text{ for } w_1 > 0 \text{ and } w_2 > 0$$

$$dG_{t+\Delta t}^n(0, w_2) = \int_{w_1=0}^{\infty} \lambda\Delta t dG_t^{n-1}(w_1, w_2-\Delta t)$$

$$dG_{t+\Delta t}^n(w_1, 0) = \int_{w_2=0}^{\infty} \mu\Delta t dG_t^{n+1}(w_1-\Delta t, w_2)$$

$$dG_{t+\Delta t}^0(w_1, 0) = (1-\lambda\Delta t)dG_t^0(w_1-\Delta t, 0) + \int_{w_2=0}^{\infty} \mu\Delta t dG_t^1(w_1-\Delta t, w_2)$$

$$dG_{t+\Delta t}^1(0, 0) = \int_{w_1=0}^{\infty} \lambda\Delta t dG_t^0(w_1, 0)$$

Substituting the functional forms found for  $dG_{\infty}^n$  into these relationships for small  $\Delta t$  also verifies that the stationary distribution has been found.

### Truncated Processes

Another interpretation of this process allows it to be used more generally or perhaps suggests making  $A_0$  relatively large. First  $\int_0^{\infty} Q_{\tau}^i dt * D^i dt$  can be interpreted as the conditional probability of a transition from states in  $A_{i-1}$  to states in  $A_{i-1}$  in  $dt$  in the stochastic process derived from the original by ignoring time spent in states in  $A_j$  for  $j > i$ . The truncated process produces probabilities which are conditional probabilities of the original

process. In the same vein  $\int_0^\infty Q_t^i d\tau * D^i * \int_0^\infty B_\tau^{i-1} dt$  can be considered as conditional probabilities for transitions from states in  $A_{i-1}$  through  $A_i$  in a truncated process in which time is discrete and measures the exits from the sets  $A_j$  for  $j = 0, i-1$ . The analysis for  $A_0$  alone is special because all exits from  $A_0$  lead to  $A_1$ . In general there are also transitions from  $A_j$  to  $A_{j-1}$  in the state just before exit process.

The use of truncated processes is very appropriate in numerical analysis when for  $j > i$  the sets  $A_j$  are identical and the transition structure does not depend on  $j$ , i.e.  $U^j = U^i$ ,  $B_t^j = B_t^i$  and  $D^j = D^i$  for  $j \geq i$ . In this case all  $Q_t^j = Q_t^{i+1}$  for  $j > i$ . Thus only a single equation need be solved for these functions. Once  $\int_0^\infty Q_t^{i+1} dt$  is known then the truncated process can be analyzed to produce  $dG_\infty^k$  for  $k = 0, i$ . The recursive relation  $dG_\infty^j = dG_\infty^{j-1} * \int_0^\infty Q_\tau^{i+1} d\tau$  starting from  $j = i+1$  and  $dG_\infty^i$  produces a complete set of  $dG_\infty^i$ . These may now be normalized to sum to 1 and the result is the limiting distribution  $dG_\infty^i$  for the original process.

This was the approach used by Winsten [5] in discussing some problems in which the upper tail of the limiting distributions are geometric. He also allowed transitions from  $A_i$  to and  $A_j$  for  $j \leq i + 1$  with probabilities which depend only of  $i-j$ . This is enough to prove the recursive relationship  $dG_\infty^{i+1} = dG_\infty^0 * R$  even in the more general context of this paper. The problem is that the equation for  $R$  becomes extremely complicated. The suggestion that single event transitions from  $A_i$  to  $A_j$  for  $j \leq i + k$  produces a  $k$  term recursive structure can also be persued. The expressions for the coefficients in this relationship also become complicated as  $k$  becomes large and the structure on the  $A_i$  becomes complex. The introduction of groups of states by the author makes this last generalization unnecessary for treating Erland  $k$  distributions as Winsten suggests.

## Applications

So far, analytic application of this structure has been restricted to systems in which the  $A_i$  are identical and discrete from some point on. The result is that the upper tail of the limiting congestion distribution is geometric with a matrix for the term ratio. Although not explicitly used in derivations this approach can provide relatively easy access to limiting distributions for systems such as  $E_j/E_k/s$  and many priority models. The intimate relation between convergent iterative calculations and the theoretical analysis make this approach useable even when it is difficult to proceed further analytically.

In developing piecewise linear processes, Gnedenko and Kovalenko [3] used the remaining length of the intervals in process as supplementary variables. The arguments presented here can easily be revised to use this representation especially if one uses rates of progress toward termination which depend on the congestion. In terms of functional forms, there seems to be no strong preference at the moment. Although this approach raises questions because  $(N(t), W(t))$  may not be observable, it does provide an analytic structure which matches that used in computer simulations. From both the philosophical and practical points of view it is important to think of simulation as one form of numerical analysis for complicated stochastic processes.
